## Extraction of Collection Elements

a) A collection with a single member: Extract the member with `ELEMENT`.

## Example

Find the price Joe charges for Bud and put the result in a variable $p$.

```
p = ELEMENT(
    SELECT s.price
    FROM Sells s
    WHERE s.bar.name = "Joe's Bar"
        AND s.beer.name = "Bud"
)
```

b) Extracting all elements of a collection, one at a time:

1. Turn the collection into a list.
2. Extract elements of a list with <list name>[i].

**Example**

Print Joe's menu, in order of price, with beers of the same price listed alphabetically.

```
L =
    SELECT s.beer.name, s.price
    FROM Sells s
    WHERE s.bar.name = "Joe's Bar"
    ORDER BY s.price, s.beer.name;

printf("Beer\tPrice\n\n");
for(i=1; i<=COUNT(L); i++)
    printf("%s\t%f\n",
        L[i].name,
        L[i].price
    );
```

## Aggregation

The five operators avg, min, max, sum, count apply to any collection, as long as the operators make sense for the element type.

## Example

Find the average price of beer at Joe's.

```
x = AVG(
    SELECT s.price
    FROM Sells s
    WHERE s.bar.name = "Joe's Bar"
);
```

- Note coersion: result of `SELECT` is technically a bag of 1-field structs, which is identified with the bag of the values of that field.

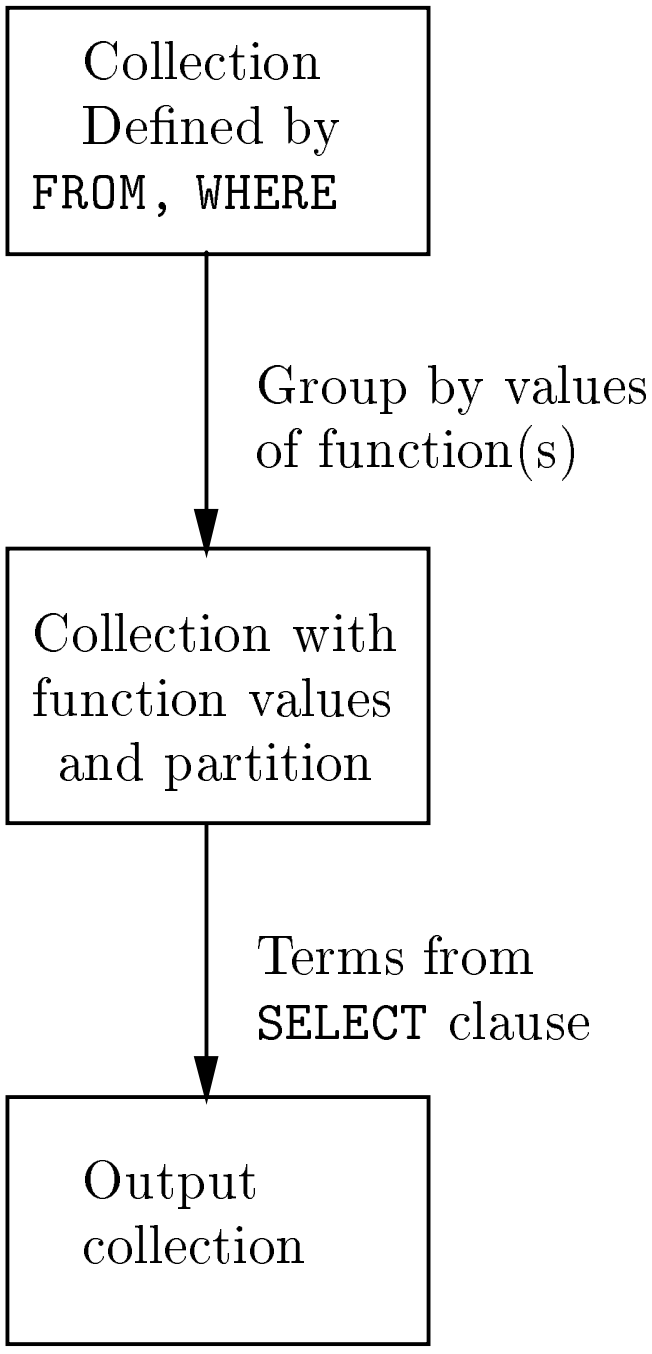
## Grouping

Recall SQL grouping, for example:

```
SELECT bar, AVG(price)
FROM Sells
GROUP BY bar;
```

- Is the `bar` value the "name" of the group, or the common value for the `bar` component of all tuples in the group?
- In SQL it doesn't matter, but in OQL, you can create groups from the values of any function(s), not just attributes.
  - ❖ Thus, groups are identified by common values, not "name."
  - ❖ Example: group by first letter of bar names (method needed).

## Outline of OQL Group-By



**Example**

Find the average price of beer at each bar.

```
SELECT barName, avgPrice: AVG(
        SELECT p.s.price
        FROM partition p
    )
FROM Sells s
GROUP BY barName: s.bar.name
```

1. Initial collection = `Sells`.

   - But technically, it is a bag of structs of the form

     `Struct(s:` $s1$`)`

     Where $s1$ is a `Sells` object. Note, the lone field is named `s`; in general, there are fields for all of the tuple variables in the `FROM` clause.

2. Intermediate collection:

   - One function: `s.bar.name` maps `Sells` objects $s$ to the value of the name of the bar referred to by $s$.
   - Collection is a set of structs of type:

```
Struct{barName: string,
    partition: Set<
        Struct{s: Sell}
    >
}
```

     For example:

```
Struct(barName = "Joe's Bar",
    partition = {s_1, ..., s_n})
```

     where $s_1, \ldots, s_n$ are all the structs with one field, named `s`, whose value is one of the `Sells` objects that represent Joe's Bar selling some beer.

3. Output collection: consists of beer-average price pairs, one for each struct in the intermediate collection.

   - Type of structures in the output:

```
Struct{barName: string,
    avgPrice: real}
```

   - Note that in the subquery of the `SELECT` clause:

```
SELECT barName, avgPrice: AVG(
        SELECT p.s.price
        FROM partition p
    )
```

     We let $p$ range over all structs in `partition`. Each of these structs contains a single field named `s` and has a `Sells` object as its value. Thus, `p.s.price` extracts the price from one of the `Sells` tuples.

   - Typical output struct:

```
Struct(barName = "Joe's Bar",
    avgPrice = 2.83)
```

## Another, Less Typical Example

Find, for each beer, the number of bars that charge a "low" price ($\leq 2.00$) and a "high" price ($\geq 4.00$) for that beer.

- Strategy: group by three things:
  1. The beer name,
  2. A boolean function that is true iff the price is low.
  3. A boolean function that is true iff the price is high.

## The Query

```
SELECT beerName, low, high,
    count: COUNT(partition)
FROM Beers b, b.soldBy s
GROUP BY beerName: b.name,
    low: s.price <= 2.00,
    high: s.price >= 4.00
```

1. Initial collection: Pairs $(b, s)$, where $b$ is a beer, and $s$ is a `Sells` object representing the sale of that beer at some bar.

   - Type of collection members:

     ```
     Struct{b: Beer, s: Sell}
     ```

2. Intermediate collection: Quadruples consisting of a beer name, booleans telling whether this group is for high, low, or neither prices for that beer, and the partition for that group.

   - The partition is a set of structs of the type:

     `Struct{b: Beer, s: Sell}`

     A typical value:

   `Struct(b: "Bud"` object,
   `s:` a `Sells` object involving Bud)

- Type of quadruples in the intermediate collection:

```
Struct{
    beerName: string,
    low: boolean,
    high: boolean,
    partition: Set<Struct{
        b: Beer,
        s: Sell
    }>
}
```

Typical structs in intermediate collection:

| beerName | low | high | partition |
|---|---|---|---|
| Bud | TRUE | FALSE | $S_{low}$ |
| Bud | FALSE | TRUE | $S_{high}$ |
| Bud | FALSE | FALSE | $S_{mid}$ |
| ... | ... | ... | ... |

where $S_{low}$ $S_{high}$, and $S_{mid}$ are the sets of beer-sells pairs $(b, s)$ where the beer is Bud and $s$ has, respectively, a low ($\leq$ 2.00), high ($\geq$ 4.00) and medium (between 2.00 and 4.00) price.

- Note the partition with `low` = `high` = `TRUE` must be empty and will not appear.

3. Output collection: The first three components of each group's struct are copied to the output, and the last (`partition`) is counted. The result:

| beerName | low | high | count |
|---|---|---|---|
| Bud | TRUE | FALSE | 27 |
| Bud | FALSE | TRUE | 14 |
| Bud | FALSE | FALSE | 36 |
| ... | ... | ... | ... |
